Abstract

Under the assumptions of an open portfolio, i.e., considering that a policyholder can transfer his policy to another insurance company and the continuous arrival of new policyholders into a portfolio which can be placed into any of the bonus classes and not only in the "starting class", we developed a model (Stochastic Vortices Model) to estimate the Long Run Distribution for a Bonus Malus System. These hypothesis render the model quite representative of the reality.

With the obtained Long Run Distribution, a few optimal bonus scales were calculated, such as Norberg’s [1979], Borgan, Hoem’s & Norberg’s [1981], Gille & Sundt’s [1989] and Andrade e Silva’s [1991].

To compare our results, since this was the first application of the model to a Bonus Malus System, we used the Classic Model for Bonus Malus and the Open Model developed by Centeno & Andrade e Silva [2001].

The results of the Stochastic Vortices and the Open Model are highly similar and quite different from those of the Classic Model.

Keywords

1 Introduction

The Bonus Malus Systems plays a fundamental role in the automobile insurance. Since the automobile insurance holds a significant part of the non-life business of many Companies, and considering the enormous and still growing competitiveness of the market, the Bonus Malus System should be
efficient, penalizing to bad drivers and simultaneously competitive. Due to market competitiveness, it is well known that, at least in Portugal, many policyholders transfer their policy to another Insurance Company, seeking lower premiums or higher discounts.

The study of Bonus Malus Systems in automobile insurance aims at finding rating systems that adjust the premium paid by the insured according to his driving experience. Unfortunately, in Portugal, the transfer of information between insurers is not efficient, which allows the rotation of policyholders which, after a claim participation during an annuity, leave their insurer and buy another policy to a competitor declaring that this will be his first insurance policy, managing to escape the penalization of the premium, and even be treated as a free claim policyholder by his next insurer. Consequently, the policyholders in the aggravated classes tend to transfer their policy to another insurer.

Another aspect taken into consideration is the fact that every year there are new policyholders, not all of which are placed in the pre-defined "starting class". In many cases, usually due to commercial goals, discounts are given to new policyholders. In other cases, when the Insurance Company requests the Tariff Certificate, the new policyholders start in an aggravated class. So, we find that it should not be assumed that all policyholders start in the same class.

Considering the Portuguese situation, that may apply to other countries, we tried to develop a model that took all these aspects into consideration. The Stochastic Vortices Model is such an alternative approach to the usual model for Bonus Malus Systems, since it allows the subscription and the annulment of policies in the portfolio and, in that way, renders it more realistic.

The Stochastic Vortices offer useful models in a great variety of situations in which the irreducible Markov chains of discrete parameter fail. These situations correspond to open populations in which there are entrances and departures. When the population is divided into sub-populations and the transition probabilities between sub-populations are invariant, these sub-populations can be considered as the transient states of an homogenous Markov chain. As we shall see, under quite general assumptions in the entrances, the limit state probabilities are obtained. The fact that the population is taken as open, renders this kind of models much more realistic than classic models based in a closed population occupying the states of an irreducible Markov chain. The limit state probabilities correspond to the long run distribution.

Using a Portuguese data set, we applied the model, obtaining the correspondent long run distribution. Afterwards, we estimated some optimal bonus scales, such as Norberg's [1979], Borgan, Hoem & Norberg's [1981], Gilde & Sundt's [1989] and Andrade e Silva's [1991].

Since this was the first application of the model, we compared our results with the Classic Model (Closed Model) for Bonus Malus Systems and also with the Open Model developed by Centeno & Andrade e Silva [2001]. The results of the Stochastic Vortices Model and the Open Model are highly similar.

After presenting the model and the data in sections two and three, section four is devoted to results.
2 Model Presentation

2.1 Stochastic Vortices

Our model applies to populations divided into sub-populations which correspond to the transient states of homogeneous Markov chains. Every element entering the population will, after a finite time span, go into a final absorbing state and cease to belong to the population.

State probabilities will be the probabilities of a randomly chosen element in the population, belonging to the different sub-populations. As we shall see, under quite general conditions, these state probabilities will converge to limit state probabilities. Thus, in our model, the long run distribution will be constituted by the limit state probabilities. As to the study of the performance of the Bonus Malus Systems (BMS) this long run distribution may be used in just the same way as when an alternative model is used.

As parting remarks we point out that:

- the state probabilities will be proportional to the mean values of the dimension of the sub-populations;
- in the application to BMS we start by considering transition probabilities which depend on a parameter $\lambda$. This parameter will have a structural distribution $F$. Thus, we will have to obtain first a $\lambda$ dependent long run distribution and then decondition it to get the unconditional long run distribution which we use in the performance analysis.

2.1.1 Transition Matrices

As said above besides $s$ transient states, as much as the sub-populations, there will be a final absorbing state. In the applications to BMS we are led to consider the transient states as constituting a communication class, but our treatment does not require this assumption. Moreover, parameter $\lambda$ will refer to the distribution of the number of claims. In the portfolio we are going to study this parameter was unidimensional but the final deconditioning can also be carried out for a vector of parameters. We also point out that transition steps will correspond to years, and that the origin of time ($t = 0$) will be the beginning of the year in which the portfolio was established.

Let $K_{1,\lambda}$ be the $s \times s$ matrix of one step transition between transient states. The full one step transition matrix will be

$$P_{T,\lambda} = \begin{pmatrix} K_{1,\lambda} & \vec{q}_{1,\lambda} \\ \vec{0}^s & 1 \end{pmatrix}$$

the last line corresponding to the absorbing state. The components of $\vec{q}_{1,\lambda}^s$ are the probabilities for the policyholders in the $s$ classes quitting after one year.

Note that, if we add the elements of a row of $K_{1,\lambda}$ with the correspondent component of $\vec{q}_{1,\lambda}^s$, the sum will have to be equal to 1. In fact, in the end of an annuity, the policyholder either remains in the portfolio, occupying the class foreseen in the transition rules or annul his policy, leaving the Company.

We now establish
Lemma 1 The $n$ steps transition matrix will be:

$$P^{(n)}_{T,\lambda} = \begin{pmatrix} K_{n,\lambda} & \bar{q}^s_{n,\lambda} \\ \vec{0}^s & 1 \end{pmatrix}$$

with:

$$K_{n,\lambda} = K^n_{1,\lambda};$$

$$\bar{q}^s_{n,\lambda} = \sum_{j=0}^{n-1} K^j_{1,\lambda} \cdot \bar{q}^s_{1,\lambda}.$$  

Proof. Since the Markov chain is homogeneous we will have $P^{(n)}_{T,\lambda} = P^n_{T,\lambda}$ and the thesis is easily established through mathematical induction once it is observed that

$$K_{n,\lambda} = K_{1,\lambda} \cdot K_{n-1,\lambda} = K_{1,\lambda} \cdot K^{n-1}_{1,\lambda}$$

$$\bar{q}^s_{n,\lambda} = K_{1,\lambda} \cdot \bar{q}^s_{n-1,\lambda} + \bar{q}^s_{1,\lambda} = K_{1,\lambda} \cdot \sum_{j=0}^{n-2} K^j_{1,\lambda} \cdot \bar{q}^s_{1,\lambda} + \bar{q}^s_{1,\lambda} = \sum_{j=0}^{n-1} K^j_{1,\lambda} \cdot \bar{q}^s_{1,\lambda} \quad \Box$$

Thus the transition probabilities in $n$ steps between the sub-populations will be the elements of the $K^n_{1,\lambda}$ matrix.

If the probabilities of a new policyholder being placed in the $s$ classes are the components of the row vector $\vec{p}'_{0,\lambda}$, the corresponding probabilities after $n$ years will be the components of

$$\vec{p}'_{s,n,\lambda} = \vec{p}'_{s,0,\lambda} \cdot K^n_{1,\lambda} \quad (2)$$

2.1.2 Limit state probabilities

Under very general conditions we have (Healy [1986])

$$K_{1,\lambda} = \sum_{l=1}^{s} \eta_{l,\lambda} \vec{\alpha}^s_{l,\lambda} \vec{\beta}^s_{l,\lambda} \quad (3)$$

where the $\eta_{l,\lambda}$ [left and right eigenvectors] of $K_{1,\lambda}$, with

$$\vec{\beta}^s_{l,\lambda} \cdot \vec{\alpha}^s_{h,\lambda} = 0; \ l \neq h \quad (4)$$

so that

$$K_{n,\lambda} = K^n_{1,\lambda} = \sum_{l=1}^{s} \eta_{l,\lambda} \vec{\alpha}^s_{l,\lambda} \vec{\beta}^s_{l,\lambda} \quad (5)$$

Now (Parzen[1965]), the transition probabilities between transient states tend to zero with the number of steps, thus

$$|\eta_{l,\lambda}| < 1; \ l = 1, \ldots, s. \quad (6)$$

Let $\theta_i$ be the mean value of admissions at the $i$-th year. To lighten the computation we assume that the admissions are at the beginning of each year. We now get
Lemma 2 The mean value for the number of policyholders in the different classes will, at the end of \( n \) years, be the components of

\[
\bar{v}_{n,\lambda} = \bar{p}_{0,\lambda} \sum_{i=0}^{n} \theta_{n-i} K_{1,\lambda}^i
\]  

(7)

Proof. The mean values we are looking for are the sum of the mean values of the policyholders in the different classes that were admitted at years \( n-i, i = 0, \ldots, n \). According to expression (2) these partial mean values will be the components of the row vectors

\[
\theta_{n-i} \cdot \bar{p}_{1,\lambda} = \theta_{n-i} \cdot \bar{p}_{0,\lambda} \cdot K_{1,\lambda}^i ; i = 0, \ldots, n
\]

and the thesis is established. □

We now introduce an assumption about the growth of the portfolio. Due to the high competitiveness of the market (at least in Portugal) we put

\[
\theta_i = \kappa (1 - e^{-\beta_i}), \quad \kappa, \beta > 0
\]  

(8)

so that the admissions will tend to a limit \( \kappa \). We point out that, due to (6), limit state probabilities exist even under more aggressive growth.

Let us establish

**Proposition 1** When (8) holds, the mean values for the number of policyholders in the different classes will be, after \( n \) years, the components of

\[
\bar{v}_{n,\lambda} = \kappa \bar{p}_{0,\lambda} \left[ \sum_{i=0}^{n} K_{1,\lambda}^i - e^{-\beta n} \sum_{i=0}^{n} (e^{\beta K_{1,\lambda}^i})^i \right]
\]  

(9)

Moreover

\[
\bar{v}_{\infty,\lambda} = \lim_{n \to \infty} \bar{v}_{n,\lambda} = \kappa \bar{p}_{0,\lambda} \sum_{l=1}^{s} \frac{1}{1-\eta_{l,\lambda}} \bar{\alpha}_{l,\lambda} \bar{\beta}_{l,\lambda}
\]  

(10)

Proof. The first part of the thesis follows from expressions (7) and (8). Going over to the second part of the thesis we have, according to (5) and (6), first

\[
\sum_{i=0}^{\infty} K_{1,\lambda}^i = \sum_{i=0}^{\infty} \sum_{l=1}^{s} \eta_{l,\lambda} \bar{\alpha}_{l,\lambda} \bar{\beta}_{l,\lambda} = \\
= \sum_{l=1}^{s} \bar{\alpha}_{l,\lambda} \bar{\beta}_{l,\lambda} \sum_{i=0}^{\infty} \eta_{l,\lambda} = \sum_{l=1}^{s} \bar{\alpha}_{l,\lambda} \bar{\beta}_{l,\lambda} \frac{1}{1-\eta_{l,\lambda}}
\]

and according to

\[
\sum_{i=0}^{n} e^{\beta (i-n)} \eta_{l,\lambda} = \frac{1 - e^{\beta (n+1)} \eta_{l,\lambda}^{n+1}}{1 - e^{\beta} \eta_{l,\lambda}} = \\
= \frac{e^{-\beta n} - e^{\beta} \eta_{l,\lambda}^{n+1}}{1 - e^{\beta} \eta_{l,\lambda}} \rightarrow 0 \text{ as } n \to \infty \text{ for } l = 1, \ldots, s.
\]
we will also get
\[ \sum_{i=0}^{n} e^{\beta(i-n)} K_i^{1,\lambda} = \sum_{l=1}^{s} \alpha_l^{\lambda} \beta_{l,\lambda}^{\prime} \sum_{i=0}^{n} e^{\beta(i-n)} \eta_{l,\lambda}^{i} \longrightarrow 0 \quad \text{as} \quad n \to \infty \quad \text{for} \quad l = 1, \ldots, s. \tag{11} \]
and the thesis is established. \( \square \)

When \( v_{\infty,\lambda}^{l,s} \) is defined, to obtain the limit state probabilities we have only to divide the components of \( v_{\infty,\lambda}^{l,s} \) by their sum. Let \( \pi_{T,\lambda}^{l,s} \) be the row vector of these limit probabilities which clearly do not depend on \( \kappa \), this is, on the upper bound for admissions.

To obtain the unconditional long run distribution we must decondition, getting
\[ \pi_{T}(j) = \int_{0}^{\infty} \pi_{T,\lambda}(j)dF(\lambda), \quad j = 1, \ldots, s. \tag{12} \]
where the \( \pi_{T,\lambda}(j) \) \( \{ \pi_{T}(j) \}, \quad j = 1, \ldots, s \), are the conditional [unconditional] limit state probabilities.

## 3 Relevant Data

We will apply our model to the portfolio of a recently established Portuguese Insurance Company. The BMS of this insurer has \( s = 20 \) classes, the premium coefficients increasing with the class index. For each claim free year the index decreases by one. The first [each of the next] claim increases the class index by three [five]. For our purposes the relevant data was

a) **Claims Frequency**

The claims frequencies (in year 2000) was

<table>
<thead>
<tr>
<th>N. accidents</th>
<th>N. policyholders</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>41,484</td>
</tr>
<tr>
<td>1</td>
<td>2,998</td>
</tr>
<tr>
<td>2</td>
<td>318</td>
</tr>
<tr>
<td>3</td>
<td>29</td>
</tr>
<tr>
<td>4</td>
<td>7</td>
</tr>
<tr>
<td>5</td>
<td>2</td>
</tr>
</tbody>
</table>

**Total** 44,838

Table 1: Claims frequencies - Year 2000

To this data it was possible to adjust a mixed Poisson distribution, the structural distribution of the \( \lambda \) parameter being Gamma. The maximum likelihood estimators for the parameters of this distribution being \( \hat{\alpha} = 0.5204150 \) and \( \hat{p} = 0.8612576 \).

b) **Admission numbers**

Since the portfolio was quite recent, having been established in the end of 1996, we assumed the values in bold on Table 2 in order to adjust a model of type \( X_i = \kappa(1-e^{-\beta i}) \), \( i = 0, 1, \ldots \) to the number of admissions.

<table>

<td>28,067</td>
<td>32,251</td>
<td>33,457</td>
<td>33,670</td>
</tr>
</tbody>
</table>

Table 2: Number of admissions per year
In carrying out the adjustment we assumed values for $\kappa$ and then used least squares to estimate $\beta$. The final pair ($\hat{\kappa}, \hat{\beta}$) chosen was the one for highest $R^2$. Thus, with $\hat{\kappa} = 40,000$ and $\hat{\beta} = 0.239947$ we obtained $R^2 = 0.987$ which can be considered an excellent fit. Figure 1 illustrates the fitness.

**Figure 1: Entrances in the BMS**

c) **Probabilities of new policies to be placed into each class**

Despite the "standard entry class" being the 10th, many new policyholders get, due to market competitiveness, a better rating. Using the available data we estimated the components of $\vec{p}_0^*$. The results are presented in Table 3.

</tbody>
</table>

Table 4: Probabilities of annulment per class

4 **Portfolio performance**

We now assess the portfolio performance using our model as well as the Open Model of Centeno \& Andrade e Silva [2001] and the Classic Closed Model.

4.1 **Long Run and Weighted Distribution**

We now consider, besides long run distribution, the weighted distribution required to apply the Borgan et al [1981] premium scale. To obtain this, we took a time horizon of 20 years, and following Centeno \& Andrade e Silva [2001], used weights given by $w_n = \frac{w_{n-1}}{1+i}$ and $\sum_{n=1}^{20} w_n = 1$, with $i = 5\%$, where $w_n$ represents the weight given to period $n$ ($n = 1, 2, \ldots$). The distributions are presented in Figure 2 with the exception of the results for Class 1 that are
shown in Table 5. The results for this singling out being that otherwise there would not be enough graphic resolution to evaluate differences in the other classes.

![Figure 2: Long run distribution and Weighted distribution](image)

The results for this singling out being that otherwise there would not be enough graphic resolution to evaluate differences in the other classes.

<td>0.441117</td>
<td>0.527541</td>
<td>0.336097</td>
</tr>
</tbody>
</table>

Table 5: Long Run and Weighted Distribution - Class 1

The results on the long run distribution, for our and Open Model are very similar and differ markedly from those of the Closed portfolio model. This last model over evaluates the probabilities for the higher classes since it does not take into consideration that policyholders tend to leave when they attain higher maluses. For the lowest class the closed model differs less. This is certainly due to many admissions being placed directly in Class 1.

As a parting remark we can point out to our and Open Model being the more realistic ones.

### 4.2 Optimal Bonus Scales

For the BMS under study several optimal bonus scales, such as those of *Norberg* [1979], *Borgan et al* [1981], *Gilde & Sundt* [1989] and *Andrade e Silva* [1991], were obtained. The results are shown in Figures 3 and 4.

![Figure 3: Norberg [1979] and Borgan et al [1981] optimal bonus scales](image)
Both our's and the Open Model have quite similar optimal bonus scales, avoiding the very low or very high premiums that are obtained when using the closed model. Thus again the two first models are to be preferred to the last one.
